## 1. Introduction

This program allows users to build analogue circuits using resistors, capacitors, and inductors (which are all classes derived from an abstract base `Component` class). A `Circuit` class can be set to be series or parallel, and any number of components can be added to it, which is then stores as a vector of components (specifically a vector of unique pointers to components). Since the `Circuit` class is inherited from the `Component` class itself, it is possible to add series circuits to parallel circuits, or vice versa, and therefore construct circuits of any topology.

In the main file of this program, a *library* of components is created, which stores different types of resistors, capacitors and inductors. These components are validated through the use of validation files, such that if the user tries to initialise a component with properties which do not match those specified in the validation file, an error message will be returned. The validation files specify a component name, like *Wirewound* for resistor, as well as a tolerance to dissipative effects, and a maximum frequency to which they can withstand [5]. Each validation file then contains maximum and minimum possible values for the resistance, capacitance and inductance respectively.

The `Component` base class contains an operating frequency `frequency` and a unique ID `component_id`, as well as a function to calculate the impedance of the component (using the complex library in C++), and its magnitude and phase difference (`get_impedance()`, `get_impedance_magnitude`, `get_phase_difference`). It also has a `base_info()` function which outputs these properties, and which is overriden in the derived classes to print the resistance, capacitance and inductance of the corresponding classes.

This program therefore gives the user an easy way of constructing circuits with nested branches and varying topologies, as well as ensuring at the same time that the components are physically meaningful, much like an undergraduate circuit labaratory where only certain types of components are available and can be used to build circuits.

## 2. Code design and implementation

We continue with this idea of the program being a simulation of a circuits lab so that the logic behind it can be more clearly explained. Consider the user of the program to be a student in an undergraduate circuits lab. This student wants to build a circuit using components from the lab's demonstrator, who has this library of components available. This library must contain components which are manufacturable, and we must have some way of enforcing this. The validation files can be seen as catalogues of manafacturable compoents from which the lab demonstrator must choose from to add to their library.

The student wants to use one of the components from the library of the lab demonstrator, but they cannot take it directly away from the lab demonstrator, as the demonstrator is the owner of that specific component. This follows from the fact that the

If they let the student take that one component which they own, then no one else in the lab could use it. In that sense it is not logical for identical components to be stored twice in the library. The student must make a copy of the component from the library, at which point they can add it to their circuit. This is done via a `clone()` function which all of the `Component`-derived classes have. They could initialise a component just by itself and then move it to the circuit, but its easier to just clone inside the circuit infrastructure.
